1 Introduction

This is a companion file both for the *mstate* package and for the Tutorial in Biostatistics: Competing risks and multi-state models (Putter et al. 2007), simply referred to henceforth as the tutorial. Emphasis in this document will be on the use of *mstate*, not on the theory of competing risks and multi-state models. The only exception is that I have added some theory about the Aalen-Johansen estimator that is implemented in *mstate* but did not appear in the tutorial. For other theory on multi-state models, and for interpretation of the results of the analyses, we will repeatedly refer to the tutorial. I will occasionally give more detail and show more analyses than in the tutorial. Also I sometimes give more details on the function in *mstate* than strictly necessary for the analyses in the tutorial, but not all features will be shown either. This file and the *mstate* package, which in turn contains all the data used in the tutorial, can be found at http://www.msbi.nl/multistate. This file is also a vignette of the *mstate* package. Type vignette("Tutorial") after having installed and loaded *mstate* to access this document within R.

I do not follow the order of the tutorial. Rather, I will start with multi-state models, Section 4 of the tutorial, and finally switch back to the special case of competing risks models. Sections 2, 3 and 4 of this document will discuss data preparation, estimation and prediction, respectively in multi-state models. In Section 5 I illustrate some functions of *mstate* designed especially for competing risks.

After installation, the *mstate* package is loaded in the usual way.

> library(mstate)

The versions of R and *mstate* used in this document are as follows:

```
> R.version$version.string
```

```
[1] "R version 3.6.1 (2019-07-05)"
```

> packageDescription("mstate", fields = "Version")

[1] "0.2.12"

2 Data preparation

The data used in Section 4 of the tutorial are 2204 patients transplanted at the EBMT between 1995 and 1998. These data are included in the *mstate* package. For (a tiny bit) more background on the data, refer to the tutorial, or type help(ebmt3).

```
> data(ebmt3)
```

> head(ebmt3)

	id	prtime	${\tt prstat}$	rfstime	${\tt rfsstat}$	dissub	age			${\tt drmatch}$		tcd
1	1	23	1	744	0	CML	>40		Gender	${\tt mismatch}$	No	TCD
2	2	35	1	360	1	CML	>40	No	gender	${\tt mismatch}$	No	TCD
3	3	26	1	135	1	CML	>40	No	gender	${\tt mismatch}$	No	TCD
4	4	22	1	995	0	AML	20-40	No	gender	${\tt mismatch}$	No	TCD
5	5	29	1	422	1	AML	20-40	No	gender	${\tt mismatch}$	No	TCD
6	6	38	1	119	1	ALL	>40	No	gender	${\tt mismatch}$	No	TCD

Let us first have a look at the covariates. For instance disease subclassification:

```
> n <- nrow(ebmt3)
> table(ebmt3$dissub)

AML ALL CML
853 447 904
> round(100 * table(ebmt3$dissub)/n)

AML ALL CML
39 20 41
```

The output of the other covariates is omitted.

```
> table(ebmt3$age)
> round(100 * table(ebmt3$age)/n)
> table(ebmt3$drmatch)
> round(100 * table(ebmt3$drmatch)/n)
> table(ebmt3$tcd)
> round(100 * table(ebmt3$tcd)/n)
```

The first step in a multi-state model analysis is to set up the transition matrix. The transition matrix specifies which direct transitions are possible (those with NA are impossible) and assigns numbers to the transitions for future reference. This can be done explicitly.

```
> tmat <- matrix(NA, 3, 3)
> tmat[1, 2:3] <- 1:2
> tmat[2, 3] <- 3
> dimnames(tmat) <- list(from = c("Tx", "PR", "RelDeath"), to = <math>c("Tx", "PR", "RelDeath")
       "PR", "RelDeath"))
> tmat
           t.o
from
            Tx PR RelDeath
  Tx
            NA
               1
  PR
            NA NA
                           3
  RelDeath NA NA
                          NA
```

Steven McKinney has kindly provided a convenient function transMat to define transition matrices. The same transition matrix may be constructed as follows.

For common multi-state models, such as the illness-death model (and competing risks models, Section 5) there is a built-in function to obtain these transition matrices more easily.

The function paths can be used to give a list of all possible paths through the multi-state model. This function should not be used for transition matrices specifying a multi-state model with loops, since there will be infinitely many paths. At the moment there is no check for the presence of loops, but this will be included shortly.

> paths(tmat)

	[,1]	[,2]	[,3]
[1,]	1	NA	NA
[2,]	1	2	NA
[3,]	1	2	3
[4,]	1	3	NA

Time in the ebmt3 data is reported in days; before doing any analysis, we first convert this to years.

```
> ebmt3$prtime <- ebmt3$prtime/365.25
> ebmt3$rfstime <- ebmt3$rfstime/365.25</pre>
```

In order to prepare data in long format, we specify the names of the covariates that we are interested in modeling. Note that I am adding prtime, which is not really a covariate, but specifying the time of platelet recovery. The purpose of this will become clear later. The specified covariates are to be retained in the dataset in long format (this is the argument keep), which we are going to call msbmt. For the original dataset ebmt3, each row corresponds to a single patient. For the long format data msbmt, each row will correspond to a transition for which a patient is at risk. See the tutorial for more detailed information.

The result is an S3 object of class *msdata* and *data.frame*. An *msdata* object is actually only a data frame with a **trans** attribute holding the transition matrix used to define it. A *print* method has been defined for *msdata* objects, which also prints the transition matrix if requested (set argument *trans* to TRUE, default is FALSE).

> head(msbmt)

In the above call of msprep, the time and status arguments specify the column names in the data ebmt3 corresponding to the three states in the multi-state model. Since all the patients start in state 1 at time 0, the time and status arguments corresponding to the first state do not really have a value. In such cases, the corresponding elements of time and status may be given the value NA. An alternative way of specifying time and status (and status as well) is as matrices of dimension status with status the number of states (and status argument doesn't need to be specified then.

The number of events in the data can be summarized with the function events.

> events(msbmt)

\$Frequencies

from	Tx	PR	${\tt RelDeath}$	no	event	${\tt total}$	entering
Tx	0	1169	458		577		2204
PR	0	0	383		786		1169
RelDeath	0	0	0		841		841

\$Proportions

to

from	Tx	PR	RelDeath	no event
Tx	0.0000000	0.5303993	0.2078040	0.2617967
PR	0.0000000	0.0000000	0.3276305	0.6723695
RelDeath	0.0000000	0.0000000	0.0000000	1.0000000

For regression purposes, we now add transition-specific covariates to the dataset. For more details on transition-specific covariates, refer to the tutorial. For a numerical covariate cov, the names of the expanded (transition-specific) covariates are cov.1, cov.2 etc. The extension .i refers to transition number i. First, we define these transition-specific covariates as a separate dataset, by setting append to FALSE.

```
> expcovs <- expand.covs(msbmt, covs[2:3], append = FALSE)
> head(expcovs)
```

	age20.40.1	age20.40.2	age20.40.3	age.40.1	age.40.2	age.40.3
1	0	0	0	1	0	0
2	0	0	0	0	1	0
3	0	0	0	0	0	1

4	0 0	0	1	(0	
5	0 0	0	0	1	L 0	
6	0 0	0	0	() 1	
	${\tt drmatchGender.mismatch.}$	1 drmatch(Gender.mi	smatch.2	drmatchGer	der.mismatch.3
1		1		0		0
2		0		1		0
3		0		0		1
4		0		0		0
5		0		0		0
6		0		0		0

We see that this expanded covariates dataset is quite large, and that the covariate names are quite long. For categorical covariates, the default names of the expanded covariates are a combination of the covariate name, the level (similar to the names of the regression coefficients that you see in regression output), followed by the transition number, in such a way that the combination is allowed as column name. If these names are too long, the user may set the value of longnames (default=TRUE) to FALSE. In this case, the covariate name is followed by 1, 2 etc, before the transition number. In case of a covariate with only two levels, the covariate name is just followed by the transition number. Confident that this will work out, we also set append to TRUE (default), which will append the expanded covariates to the dataset.

> msbmt <- expand.covs(msbmt, covs, append = TRUE, longnames = FALSE)
> head(msbmt)

An object of class 'msdata'

4	0	0	0	0	0 0.09582478 0.00000000 0.00000000
5	0	0	0	0	0 0.00000000 0.09582478 0.00000000
6	0	0	0	0	0 0.00000000 0.00000000 0.09582478

The names indeed are quite a bit shorter. The downside however is that we need to remember for ourselves to which category for instance the number 1 in age1.2 corresponds (age 20-40 with ≤ 20 as reference category).

3 Estimation

After having prepared the data in long format, estimation of covariate effects using Cox regression is straightforward using the *coxph* function of the *survival* package. This is not at all a feature of the *mstate* package, other than that *msprep* has facilitated preparation of the data. Let us consider the Markov model, where we assume different effects of the covariates for different transitions; hence we use the transition-specific covariates obtained by *expand.covs*. The delayed entry aspect of this model for transition 3 (see discussion in the tutorial) is achieved by specifying Surv(Tstart, Tstop, status), where (this is reflected in the long format data) Tstart is the time of entry in the state, and Tstop the event or censoring time, depending on the value of status. We consider first the model without any proportionality assumption on the baseline hazards; this is achieved by adding strata(trans) to the formula, which estimates separate baseline hazards for different values of trans (the transitions). The results appear in the left column of Table III of the tutorial.

```
> c1 <- coxph(Surv(Tstart, Tstop, status) ~ dissub1.1 + dissub2.1 +</pre>

Likelihood ratio test=117.7 on 18 df, p=< 2.2e-16 n= 5577, number of events= 2010

The interpretation is discussed in the tutorial.

The next model considered is the Markov model where the transition hazards into relapse or death (these correspond to transitions 2 and 3) are assumed to be proportional. For this purpose transition 1 (transplantation \rightarrow platelet recovery) belongs to one stratum and transitions 2 (transplantation \rightarrow relapse/death) and 3 (platelet recovery \rightarrow relapse/death) belong to a second stratum. Transitions 2 and 3 have the same receiving state, hence the same value of to, so the two strata can be distinguished by the variable to in our dataset. In order to distinguish between transitions 2 and 3, we introduce a time-dependent covariate pr that indicates whether or not platelet recovery has already occurred. For transition 2 (Tx \rightarrow RelDeath) the value of pr equals 0, while for transition 3 (PR \rightarrow RelDeath) the value of pr equals 1. Results are found in the middle of Table III of the tutorial.

Likelihood ratio test=135.3 on 19 df, p=< 2.2e-16 n= 5577, number of events= 2010

For a discussion of the results we again refer to the tutorial. The hazard ratio of pr (0.685) and its p-value (0.073) indicate a trend-significant beneficial effect of platelet recovery on relapse-free survival. Later on we will look at the corresponding baseline transition intensities for these two models and see as a graphical check that the assumption of proportionality of the baseline hazards for transitions 2 and 3 is reasonable. This can also be tested formally using the function cox.zph (part of the survival package, not of mstate).

> cox.zph(c2)

There is no evidence of non-proportionality of the baseline transition intensities of transitions $2 \ (p=0.496 \ \text{for pr})$. There is strong evidence that the proportional hazards assumption for dissub2 (CML vs AML) is violated, at least for the transitions into relapse and death. This makes sense, clinically, since CML and AML are two diseases with completely different biological pathways. It would have been much better to study separate multi-state models for the three

disease subclassifications. However, since the purpose of this manuscript is to illustrate the use of *mstate*, we will blatantly ignore the clear evidence of non-proportionality for the disease subclassifications.

Building on the Markov PH model, we can investigate whether the time at which a patient arrived in state 2 (PR) influences the subsequent RFS rate, that is, the transition hazard of $PR \rightarrow RelDeath$. Here the purpose of expanding prtime becomes apparent. Since prtime only makes sense for transition 3 (PR \rightarrow RelDeath), we need the transition-specific covariate of prtime for transition 3, which is prtime.3. The corresponding model is termed the "state arrival extended Markov PH" model in the tutorial, and appears on the right of Table III.

prtime.3
```

Likelihood ratio test=135.5 on 20 df, p=< 2.2e-16 n= 5577, number of events= 2010

The influence of the time at which platelet recovery occurred seems small and is not significant (p=0.62, last row).

The clock-reset models may be obtained very similarly to those of the clock-forward models. The only difference is that Surv(Tstart, Tstop, status) is replaced by Surv(time, status). This reflects the fact (recall that in our long format data each row corresponds to a transition) that for each transition the time starts at 0, rather than Tstart, the time since start of study at which the state has been entered. We will only show the code, not the output; the reader may try this for him-or herself.

4 Prediction

In order to obtain prediction probabilities in the context of the Markov multi-state models discussed in the previous section, basically two steps are involved. The first is to use the estimated parameters and baseline transition hazards and the covariate values of a patient of interest, to obtain patient-specific transition hazards for that patient, for each of the transitions in the multi-state model. This is what the function msfit is designed to do. The second step is to use the resulting patient-specific transition hazards (and variances and covariances) as input for probtrans to obtain (patient-specific) transition probabilities.

I will first show how msfit can be used to obtain the baseline hazards associated with the Markov stratified and PH models. The hazards of the Markov stratified models (and their variances and covariates) are obtained by first creating a new dataset containing the (expanded) covariates along with their values (in this case 0). This is very similar to the use of survfit from the survival package. The important difference is that for one patient, this newdata data frame needs to have exactly one line for each transition. When transition-specific covariates have been used in the model, the easiest way to obtain such a data frame is to first create a data frame with the basic covariates and then using expand.covs to obtain the transition-specific covariates. Since expand.covs expects an msdata object, we set the class of the newdata data to msdata explicitly. We also copy the levels of the categorical covariates before expanding, although this is not really necessary here.

```
> newd <- data.frame(dissub = rep(0, 3), age = rep(0, 3), drmatch = rep(0,
+ 3), tcd = rep(0, 3), trans = 1:3)
> newd$dissub <- factor(newd$dissub, levels = 0:2, labels = levels(ebmt3$dissub))
> newd$age <- factor(newd$age, levels = 0:2, labels = levels(ebmt3$age))
> newd$drmatch <- factor(newd$drmatch, levels = 0:1, labels = levels(ebmt3$drmatch))
> newd$tcd <- factor(newd$tcd, levels = 0:1, labels = levels(ebmt3$tcd))</pre>
```

```
> attr(newd, "trans") <- tmat
> class(newd) <- c("msdata", "data.frame")</pre>
> newd <- expand.covs(newd, covs[1:4], longnames = FALSE)
> newd$strata = 1:3
> newd

```

The last command where the column strata is added is important and points to a second major difference between survfit and msfit. The newdata data frame needs to have a column strata specifying to which stratum in the coxph object each transition belongs. Here each transition corresponds to a separate stratum, so we specify 1, 2, and 3.

To obtain an estimate of the baseline cumulative hazard for the "stratified hazards" model, msfit can be called with the first Cox model, c1, as input model, and newd as newdata argument.

```
> msf1 <- msfit(c1, newdata = newd, trans = tmat)</pre>
```

The result is an object of class msfit, which is a list with three items, Haz, varHaz, and trans. The item trans records the transition matrix used when constructing the msfit object. Haz contains the estimated cumulative hazard for each of the transitions for the particular patient specified in newd, while varHaz contains the estimated variances of these cumulative hazards, as well as the covariances for each combination of two transitions. All are evaluated at the time points for which any event in any transition occurs, possibly augmented with the largest (non-event) time point in the data. The summary method for msfit objects is most conveniently used for a summary. If we also would like to have a look at the covariances, we could set the argument variance equal to TRUE.

```
> summary(msf1)
```

Note that the covariances of the estimated cumulative hazards are practically (apart from rounding errors) 0. Theoretically, they should be 0, because with separate strata and separate covariate effects for the different transitions, the estimates of the three transitions could in fact have been estimated as three separate Cox models (this would give exactly the same results).

The estimated baseline cumulative hazards for the Markov PH model are obtained in mostly the same way. The only exception is the specification of the *strata* argument in newd. Instead of taking the values 1, 2, and 3, for the three transitions, they take values 1, 2, 2, to indicate that transition 1 corresponds to stratum 1, and both transitions 2 and 3 correspond to stratum 2 (the order of the strata as defined in the coxph object). Also the time-dependent covariate pr needs to be included, taking the value 0 for transitions 1 and 2, and 1 for transition 3.

Note that the estimated cumulative hazards and variances for transition 1 are identical to those from msf1. We saw earlier that the estimated regression coefficients were also identical for the Markov stratified and the Markon PH models. Note also that the variance of the cumulative hazard of transition 3 (and 2, not shown) is smaller than with msf1. The cumulative hazard estimates of transitions 1 and 2 are still uncorrelated (and 1 and 3), but those of transitions 2 and 3 are correlated now, because they share a common baseline.

Let us compare the baseline hazards of the Markov stratified and PH models graphically. For this we use the *plot* method for *msfit* objects. Figure 1 corresponds to Figure 14 in the tutorial.

Define the multi-state model as X(t), a random process taking values in $1, \ldots, S$ (S being the number of states). We are interested in estimating so called transition probabilities $P_{gh}(s,t) = P(X(t) = h \mid X(s) = g)$, possibly depending on covariates. For instance, $P_{13}(0,t)$ indicates the probability of having relapsed/died (state 3) by time t, given that the individual was alive without relapse or platelet recovery (state 1) at time s = 0. By fixing s and varying t, we can predict the future behavior of the multi-state model given the present at time s. For Markov models, these probabilities will depend only on the state at time s, not on what happened before. For these Markov models there is a powerful relation between these transition probabilities and the transition intensities, given by

(1)
$$\mathbf{P}(s,t) = \prod_{(s,t]} (\mathbf{I} + d\mathbf{\Lambda}(u))$$

Here $\mathbf{P}(s,t)$ is an $S \times S$ matrix with as (g,h) element the $P_{gh}(s,t)$ in which we are interested, and $\mathbf{\Lambda}(t)$ is an $S \times S$ matrix with as off-diagonal (g,h) elements the transition intensities $\Lambda_{gh}(t)$ of transition $g \to h$. If such a direct transition is not possible, then $\Lambda_{gh}(t) = 0$. The diagonal elements of $\mathbf{\Lambda}(t)$ are defined as $\Lambda_{gg}(t) = -\sum_{h \neq g} \Lambda_{gh}(t)$, i.e. as minus the sum of the

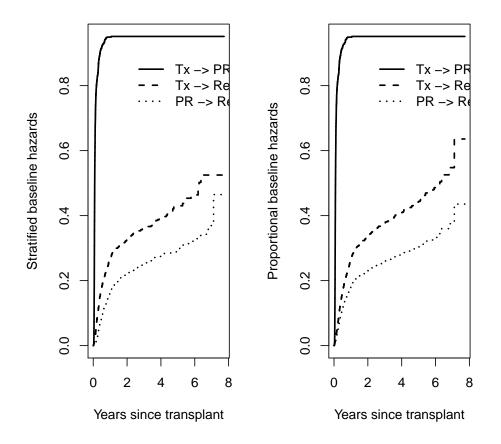

Figure 1: Baseline cumulative hazard curves for the EBMT illness-death model. On the left the Markov stratified hazards model, on the right the Markov PH model.

transition intensities of the transitions out from state g. Finally, \mathbf{I} is the $S \times S$ identity matrix. Equation (1) describes a theoretical relation between the true underlying transition intensities and transition probabilities. The product is a so called product integral (Andersen et al. 1993) when the transition intensities are continuous.

We already have estimates of all the transition intensities. If we gather these in a matrix and plug them in equation (1), we get

(2)
$$\hat{\mathbf{P}}(s,t) = \prod_{s < u < t} \left(\mathbf{I} + d\hat{\mathbf{\Lambda}}(u) \right)$$

as an estimate of the transition probabilities. This estimator is called the Aalen-Johansen estimator, and it is implemented in probtrans. By working with matrices, we immediately get all the transition probabilities from all the starting states g to all the receiving states h in one go. When we fix s, we can calculate all these transition probabilities by forward matrix multiplications using the simple recursive relation

$$\hat{\mathbf{P}}(s,t+) = \hat{\mathbf{P}}(s,t) \cdot \left(\mathbf{I} + d\hat{\mathbf{\Lambda}}(t+)\right)$$
.

Andersen et al. (1993) and de Wreede et al. (2009) also describe recursive formulas for the covariance matrix of $\hat{\mathbf{P}}(s,t)$, with and without covariates, which are implemented in *mstate*.

Let us see all this theory in action and let us recreate Figure 15 of the tutorial. For this we need to calculate transition probabilities for a baseline patient, based on the Markov PH model. We thus use msf2 as input for probtrans. By default, probtrans uses forward prediction, which means that s is kept fixed and t > s. The argument predt specifies either s or t. In this case (forward prediction) it specifies s. From version 0.2.3 on, probtrans no longer needs a trans argument, but takes that from the trans item of the msfit object.

> pt <- probtrans(msf2, predt = 0)

The result of probtrans is a probtrans object, which is a list, where item [[i]] contains predictions from state i. Each item of the list is a data frame with time containing all event time points, and pstate1, pstate2, etc the probabilities of being in state 1, 2, etc, and finally se1, se2 etc the standard errors of these estimated probabilities. The item [[3]] contains predictions $\hat{P}_{3h}(0,t)$ (we chose s=0) starting from the RelDeath state, which is absorbing.

> head(pt[[3]])

	time	pstate1	pstate2	pstate3	se1	se2	se3
1	0.00000000	0	0	1	0	0	0
2	0.002737851	0	0	1	0	0	0
3	0.008213552	0	0	1	0	0	0
4	0.010951403	0	0	1	0	0	0
5	0.016427105	0	0	1	0	0	0
6	0.019164956	0	0	1	0	0	0

> tail(pt[[3]])

	time	pstate1	pstate2	pstate3	se1	se2	se3
501	6.253251	0	0	1	0	0	0
502	6.357290	0	0	1	0	0	0
503	6.362765	0	0	1	0	0	0
504	6.798084	0	0	1	0	0	0
505	7.110198	0	0	1	0	0	0
506	7.731691	0	0	1	0	0	0

We see that these prediction probabilities are not so interesting; the probabilities are all 0 or 1, and, since there is no randomness, all the SE's are 0. Item [[2]] contains predictions $\hat{P}_{2h}(0,t)$ from state 2.

It is easier to use the *summary* method for *probtrans* objects. The user may specify a *from* argument, specifying from which state the predictions are to be printed. The *summary* method prints a selection, the *head* and *tail* by default unless there are fewer than 12 time points. When *complete* is set to TRUE, predictions for all time points are printed. If the *from* argument is missing in the function call, then predictions from all states are printed.

```
> summary(pt, from = 2)
```

But we see that we do not have enough information to create Figure 15 of the tutorial, since the probability of the relapse/death state (pstate3) does not distinguish between relapse/death before or after platelet recovery. The remedy is actually easy in this case. Consider a different multi-state model with two RelDeath states, the first one (state 3) after platelet recovery, the second one (state 4) without platelet recovery. The transition matrix of this multi-state model is defined as

```
> tmat2 < -transMat(x = list(c(2, 4), c(3), c(), c()))
> tmat2
         t.o
from
           State 1 State 2 State 3 State 4
  State 1
                NΑ
                          1
                                  NΑ
  State 2
                NA
                         NA
                                   3
                                          NA
  State 3
                NA
                         NA
                                  NA
                                          NA
  State 4
                NA
                         NA
                                  NA
                                          NA
```

The multi-state model has four states and the same three transitions as before. If we apply probtrans to this new multi-state model with the same estimated cumulative hazards and standard errors as before, we get exactly what we want. Thus, we just have to call probtrans with the old msf2 and the new tmat2. From version 0.2.3 on, since the transition matrix is in the msfit object, we just need to replace the trans item of msf2 by tmat2. In the elements of the resulting lists, pstate3 will indicate the probability of relapse/death after platelet recovery and pstate4 the probability of relapse/death without platelet recovery.

```
> msf2$trans <- tmat2

```

The reader may check that the pstate3 and pstate4 probabilities of this new Aalen-Johansen estimator sum up to the pstate3 probability of the result of the previous call to probtrans, and that the pstate1 and pstate2 probabilities are unchanged.

Figure 2 contains a plot of pt1. For this we use the plot method for problems objects.

```
> plot(pt, ord = c(2, 3, 4, 1), lwd = 2, xlab = "Years since transplant",
+ ylab = "Prediction probabilities", cex = 0.75, legend = c("Alive in remission, no PR",
+ "Alive in remission, PR", "Relapse or death after PR",
+ "Relapse or death without PR"))
```

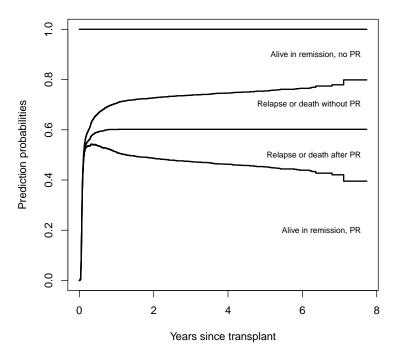

Figure 2: Stacked prediction probabilities at s=0 for a reference patient. PR stands for platelet recovery

The argument from determines from which state the transition probabilities are to be plotted. The default is from state 1, which is what we want, so the from argument is omitted here. The default type of the plot method for probtrans objects is a "stacked" plot, for which the difference between two adjacent lines represents the probability of being in a state. The argument ord specifies the order of the states of which the probabilities are stacked. The present order, 2, 3, 4, 1, allows states 2 and 3 to be combined visually (states with platelet recovery) and states 3 and 4 (death states). Other plot types are "filled", which is like "stacked", but uses colors to fill the space between adjacent lines, "single", which simply plots the transition probabilities as different lines in a single plot, and "separate", which uses separate plots for the transition probabilities.

To obtain the predictions $\hat{P}_{1h}(s,t)$ for s=0.5, which are plotted in Figure 16 of the tutorial, we simply change the value of *predt* in the call to *probtrans*.

```
> pt <- probtrans(msf2, predt = 0.5)
> summary(pt, from = 1)
An object of class 'probtrans'
```

Prediction from state 1 (head and tail):

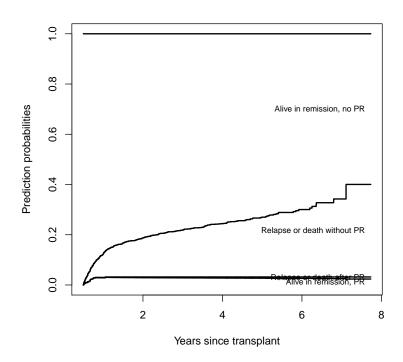

Figure 3: Stacked prediction probabilities at s = 0.5 for a reference patient

335 0.005060910 0.07944552

The result now contains only time points $t \geq 0.5$. Figure 3 contains a plot of pt1.

```
> plot(pt, ord = c(2, 3, 4, 1), lwd = 2, xlab = "Years since transplant",
+ ylab = "Prediction probabilities", cex = 0.75, legend = c("Alive in remission, no PR",
+ "Alive in remission, PR", "Relapse or death after PR",
+ "Relapse or death without PR"))
```

Figure 17 of the tutorial distinguishes between three patients, one being the good old (or rather young) reference patient, for which we have already calculated the probabilities, one for a patient in the age category 20-40, and one for a patient older than 40. To obtain prediction probabilities for the latter two patients as well, we have to repeat part of the calculations, changing only the value of age in the newdata data frame.

```
> msf2$trans <- tmat
> msf.20 <- msf2 # copy msfit result for reference (young) patient
> newd <- newd[,1:5] # use the basic covariates of the reference patient
> newd2 <- newd
> newd2$age <- 1
> newd2$age <- factor(newd2$age,levels=0:2,labels=levels(ebmt3$age))
> attr(newd2, "trans") <- tmat
> class(newd2) <- c("msdata","data.frame")
> newd2 <- expand.covs(newd2,covs[1:4],longnames=FALSE)
> newd2$trata=c(1,2,2)
> newd2$pr <- c(0,0,1)</pre>
```

```
> msf.2040 <- msfit(c2, newdata=newd2, trans=tmat)</pre>
> newd3 <- newd
> newd3$age <- 2
> newd3$age <- factor(newd3$age,levels=0:2,labels=levels(ebmt3$age))</pre>
> attr(newd3, "trans") <- tmat
> class(newd3) <- c("msdata","data.frame")</pre>
> newd3 <- expand.covs(newd3,covs[1:4],longnames=FALSE)
> newd3$strata=c(1,2,2)
> newd3$pr <- c(0,0,1)
> msf.40 <- msfit(c2, newdata=newd3, trans=tmat)</pre>
> pt.20 <- probtrans(msf.20,predt=0) # original young (<= 20) patient
> pt.201 <- pt.20[[1]]; pt.202 <- pt.20[[2]]</pre>
> pt.2040 <- probtrans(msf.2040,predt=0) # patient 20-40
> pt.20401 <- pt.2040[[1]]; pt.20402 <- pt.2040[[2]]</pre>
> pt.40 <- probtrans(msf.40,predt=0) # patient > 40
> pt.401 <- pt.40[[1]]; pt.402 <- pt.40[[2]]
The 5-years transition probabilities P_{13}(0,5) and P_{23}(0,5) are estimated as 0.30275 and 0.26210
respectively.

Figure 4 shows relapse-free survival probabilities without distinction between before or after
platelet recovery, so we can use the first transition matrix tmat. The probabilities we want are
1 - \hat{P}_{13}(0,t) and 1 - \hat{P}_{23}(0,t), the first one conditioning on being in state 1 (transplantation,
i.e. no PR), the second in being in state 2 (PR).
> plot(pt.201$time, 1 - pt.201$pstate3, ylim = c(0.425, 1), type = "s",

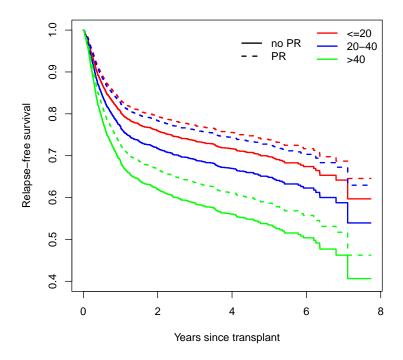

Figure 4: Predicted relapse-free survival probabilities for three patients in different age categories, given platelet recovery (dashed) and given no platelet recovery (solid). The time of prediction was at transplant (note: in the tutorial this was at 1 month after transplant).

It is also possible to do prediction with a fixed horizon. This should not be understood as attempting to predict the past. It means that in our prediction probabilities $P_{gh}(s,t)$, we fix t, a time horizon, and we want to study how $P_{gh}(s,t)$ changes as more and more information on a patient becomes available. From a computational point of view this just means that the order of the matrix multiplication in (2) is reversed. We will plot $1 - \hat{P}_{13}(s,5)$ and $1 - \hat{P}_{23}(s,5)$, the 5-years relapse-free survival probabilities given that the patient is in state 1 (no PR) and in state 2 (PR), respectively, for the same three patients as before.

```
> pt.20 <- probtrans(msf.20, direction = "fixedhorizon", predt = 5)

Here item [[1]] gives estimates $\hat{P}_{1h}(s,5)$ and [[2]] gives estimates $\hat{P}_{2h}(s,5)$. For item [[g]], the column time gives the different values of s and pstate1 etc give the estimated probabilities of being in state 1 etc at 5 years, conditional on being in state g at time s. In pt.201 we recognize at time (s)=0) 0.30275 as $\hat{P}_{1h}(0,5)$ and in pt.202 we see 0.26210 as $\hat{P}_{2h}(0,5)$. The backward transition probabilities for the other two patients are calculated similarly.

```
> pt.2040 <- probtrans(msf.2040, direction = "fixedhorizon", predt = 5)
> pt.20401 <- pt.2040[[1]]
> pt.20402 <- pt.2040[[2]]
> pt.40 <- probtrans(msf.40, direction = "fixedhorizon", predt = 5)
> pt.401 <- pt.40[[1]]
> pt.402 <- pt.40[[2]]</pre>
```

As mentioned before, in s = 0, these probabilities are the same as the five-years probabilities of Figure 4, and as s approaches 5, the probabilities approach 1, since both $\hat{P}_{13}(s,5)$ and $\hat{P}_{23}(s,5)$ approach 0. Figure 5 shows 5-years relapse-free survival probabilities, both with and without platelet recovery, with the prediction time s varying.

```
> plot(pt.201$time, 1 - pt.201$pstate3, ylim = c(0.425, 1), type = "s",
+ lwd = 2, col = "red", xlab = "Years since transplant", ylab = "Relapse-free survival".
```

Backward prediction

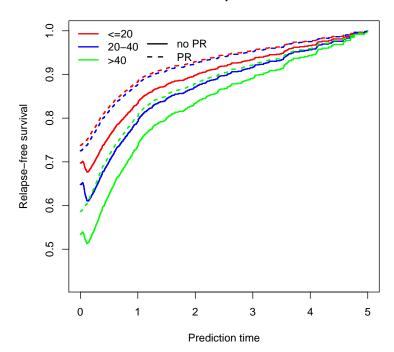

Figure 5: Predicted probabilities of 5-years relapse-free survival, conditional on being alive without relapse with (PR) and without platelet recovery (no PR). Patients in three age categories.

5 Competing risks

The data used in Section 3 of the tutorial is available in *mstate* under the name aidssi. See the help file for more information.

```
> data(aidssi)
> si <- aidssi # Just a shorter name
> head(si)
```

```

> table(si\$status)

0 1 2 107 114 108

To prepare data in long format, it is possible to use <code>msprep</code>. In this case there is not a huge advantage in using <code>msprep</code>; the long data may just as easily be prepared directly. Nevertheless we will illustrate the use of <code>msprep</code> to obtain data in long format. The function <code>trans.comprisk</code> prepares a transition matrix for competing risks models. The first argument is the number of causes of failure; in the <code>names</code> argument a character vector of length three (the total number of states in the multi-state model including the failure-free state) may be given. The transition matrix has three states with stte 1 being the failure-free state and the subsequent sttes representing the different causes of failure.

```
> tmat <- trans.comprisk(2, names = c("event-free", "AIDS", "SI"))
> tmat
```

to

 from
 event-free
 AIDS
 SI

 event-free
 NA
 1
 2

 AIDS
 NA
 NA
 NA

 SI
 NA
 NA
 NA

Now follows the actual call to msprep.

```
> si$stat1 <- as.numeric(si$status == 1)
> si$stat2 <- as.numeric(si$status == 2)
> silong <- msprep(time = c(NA, "time", "time"), status = c(NA,
+ "stat1", "stat2"), data = si, keep = "ccr5", trans = tmat)</pre>
```

We can use events to check whether the number of events from original data (si) corresponds with long data.

> events(silong)

\$Frequencies

to

from event-free AIDS SI no event total entering 114 108 107 329 event-free 0 AIDS 0 0 114 114 0 0 SI 0 0 108 108

\$Proportions

to

```
from event-free AIDS SI no event event-free 0.0000000 0.3465046 0.3282675 0.3252280 AIDS 0.0000000 0.0000000 0.0000000 1.0000000 SI 0.0000000 0.0000000 0.0000000 1.0000000
```

For the regression analyses to be performed later we add transition-specific covariates. In the context of competing risks one could call them cause-specific covariates. Since the factor levels of CCR5 are quite short we keep the default setting (TRUE) of *longnames*.

```
> silong <- expand.covs(silong, "ccr5")
> silong[1:8, ]
```

An object of class 'msdata'

Data:

	id	from	to	trans	Tstart	Tstop	time	status	ccr5	ccr5WM.1	ccr5WM.2

To illustrate the fact that naive Kaplan-Meiers are biased estimators of the probabilities of failing from the different causes of failure, we just make use of the functions in the *survival* package. I am using *coxph* below, probably this could be done quicker.

```
> c1 <- coxph(Surv(time, status) ~ 1, data = silong, subset = (trans ==
+ 1), method = "breslow")
> c2 <- coxph(Surv(time, status) ~ 1, data = silong, subset = (trans ==
+ 2), method = "breslow")
> h1 <- survfit(c1)
> h1 <- data.frame(time = h1$time, surv = h1$surv)
> h2 <- survfit(c2)
> h2 <- data.frame(time = h2$time, surv = h2$surv)</pre>
```

These naive Kaplan-Meier curves are shown in Figure 6 (Figure 2 in the tutorial). The Kaplan-Meier estimate of AIDS is plotted as a survival curve, while that of SI appearance is shown as a distribution function. There is some extra code to chop the time at 13 years. This was just done to make the picture prettier.

```
> idx1 <- (h1\$time<13) # this restricts the plot to the first 13 years

> plot(c(0,h1\$time[idx1],13),c(1,h1\$surv[idx1],min(h1\$surv[idx1])),type="s",

+ xlim=c(0,13),ylim=c(0,1),xlab="Years from HIV infection",ylab="Probability",lwd=2)

> idx2 <- (h2\$time<13)

> lines(c(0,h2\$time[idx2],13),c(0,1-h2\$surv[idx2],max(1-h2\$surv[idx2])),type="s",lwd=2)

> text(8,0.71,adj=0,"AIDS")

> text(8,0.32,adj=0,"SI")
```

Cumulative incidence functions can be computed using the function Cuminc. It takes as main arguments time and status, which can be provided as vectors

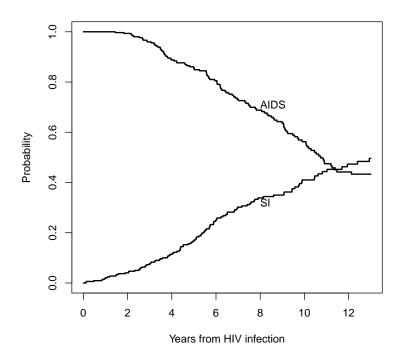

Figure 6: Estimated survival curve for AIDS and probability of SI appearance, based on the naive Kaplan-Meier estimator.

> ci <- Cuminc(time = si\$time, status = si\$status)

or, alternatively, as column names representing time and status, along with a *data* argument containing these column names.

```
> ci <- Cuminc(time = "time", status = "status", data = aidssi)
```

The result is a data frame containing the failure-free probabilities (Surv) and the cumulative incidence functions with their standard errors. Other arguments allow to specify the codes for the causes of failure and a group identifier.

> head(ci)

> idx2 <- (h2$time < 13)
> lines(c(0, h2\$time[idx2], 13), c(0, 1 - h2\$surv[idx2], max(1 - h
                           h2\$surv[idx2])), type = "s", 1wd = 2, col = 8)
> text(8, 0.77, adj = 0, "AIDS")
> text(8, 0.275, adj = 0, "SI")
The stacked plots of Figure 4 of the tutorial are shown in Figure 8.
> idx0 <- (ci$time < 13)
> plot(c(0, ci$time[idx0]), c(0, ci$CI.1[idx0]), type = "s", xlim = c(0,

 ylim = c(0, 1), xlab = "Years from HIV infection", ylab = "Probability",

                            1wd = 2
> lines(c(0, ci$time[idx0]), c(0, ci$CI.1[idx0] + ci$CI.2[idx0]),
                            type = "s", lwd = 2)
> text(13, 0.5 * max(ci$CI.1[idx0]), adj = 1, "AIDS")
> text(13, max(ci$CI.1[idx0]) + 0.5 * max(ci$CI.2[idx0]), adj = 1,
                            "SI")
> text(13, 0.5 + 0.5 * max(ci$CI.1[idx0]) + 0.5 * max(ci$CI.2[idx0]),
                            adj = 1, "Event-free")
```

Regression

The section on regression in the tutorial already shows some R code and occasional output. Because of the fact that I used msprep to prepare the long data, occasionally there will be very small differences with the code in the tutorial. We start with regression on cause-specific hazards. Using the original dataset, we can apply ordinary Cox regression for cause 1 (AIDS), taking only the AIDS cases as events. This is done by specifying status==1 below (observations with status=0 (true censorings) and status=2 (SI) are treated as censorings). Similarly for cause 2 (SI appearance), where status==2 indicates that only failures due to SI appearance are to be treated as events.

```
> coxph(Surv(time, status == 1) ~ ccr5, data = si) # AIDS
```

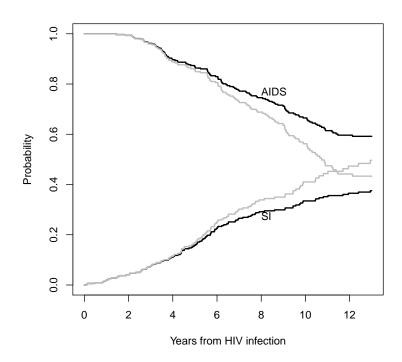

Figure 7: Estimates of probabilities of AIDS and SI appearance, based on the naive Kaplan-Meier (grey) and on cumulative incidence functions (black).

```
Call:
coxph(formula = Surv(time, status == 1) ~ ccr5, data = si)
          coef exp(coef) se(coef)
ccr5WM -1.2358
                  0.2906
                           0.3071 -4.024 5.72e-05
Likelihood ratio test=21.98 on 1 df, p=2.756e-06
n= 324, number of events= 113
   (5 observations deleted due to missingness)
> coxph(Surv(time, status == 2) ~ ccr5, data = si) # SI appearance
Call:
coxph(formula = Surv(time, status == 2) ~ ccr5, data = si)
          coef exp(coef) se(coef)
                                              p
ccr5WM -0.2542
                  0.7755
                           0.2380 -1.068 0.286
Likelihood ratio test=1.19 on 1 df, p=0.2748
n= 324, number of events= 107
   (5 observations deleted due to missingness)
```

The same analysis can be performed using the long format dataset silong in several ways. For instance, as separate Cox regressions.

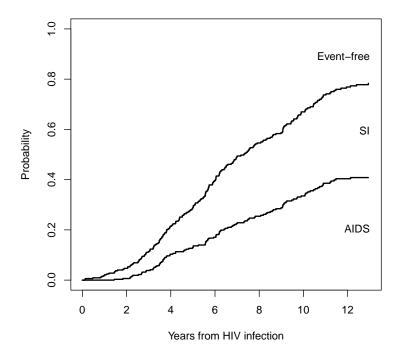

Figure 8: Cumulative incidence curves of AIDS and SI appearance. The cumulative incidence functions are stacked; the distances between two curves represent the probabilities of the different events.

```
> coxph(Surv(time, status) ~ ccr5, data = silong, subset = (trans ==
      1), method = "breslow")
Call:
coxph(formula = Surv(time, status) ~ ccr5, data = silong, subset = (trans ==
    1), method = "breslow")
          coef exp(coef) se(coef)
                 ccr5WM -1.2358
Likelihood ratio test=21.98 on 1 df, p=2.758e-06
n= 324, number of events= 113
   (5 observations deleted due to missingness)
> coxph(Surv(time, status) ~ ccr5, data = silong, subset = (trans ==
     2), method = "breslow")
Call:
coxph(formula = Surv(time, status) ~ ccr5, data = silong, subset = (trans ==
    2), method = "breslow")
          coef exp(coef) se(coef)
                 0.7755
                         0.2380 -1.068 0.286
ccr5WM -0.2542
Likelihood ratio test=1.19 on 1 df, p=0.2748
n= 324, number of events= 107
   (5 observations deleted due to missingness)
And in a single analysis, using the expanded covariates.
> coxph(Surv(time, status) ~ ccr5WM.1 + ccr5WM.2 + strata(trans),
     data = silong)
coxph(formula = Surv(time, status) ~ ccr5WM.1 + ccr5WM.2 + strata(trans),
   data = silong)
            coef exp(coef) se(coef)
                   0.2906
ccr5WM.1 -1.2358
                            0.3071 -4.024 5.72e-05
                    0.7755
ccr5WM.2 -0.2542
                            0.2380 -1.068
Likelihood ratio test=23.17 on 2 df, p=9.294e-06
n= 648, number of events= 220
   (10 observations deleted due to missingness)
The same model, but now using a covariate by cause interaction.
> coxph(Surv(time, status) ~ ccr5 * factor(trans) + strata(trans),
     data = silong)
```

```
Call:
coxph(formula = Surv(time, status) ~ ccr5 * factor(trans) + strata(trans),
    data = silong)

    coef exp(coef) se(coef) z p
```

ccr5WM -1.2358 0.2906 0.3071 -4.024 5.72e-05 factor(trans)2 NA NA 0.0000 NA NA ccr5WM:factor(trans)2 0.9816 2.6688 0.3886 2.526 0.0115

Likelihood ratio test=23.17 on 2 df, p=9.294e-06 n= 648, number of events= 220 (10 observations deleted due to missingness)

(10 Obbet vactions deferred due to missinghess)

In the model below we assume that the effect of CCR5 on the two cause-specific hazards is equal. The significant effect of the interaction in the model we just saw indicates that this is not a good idea. But, again, this is just for educational purposes.

```
> coxph(Surv(time, status) ~ ccr5 + strata(trans), data = silong)
```

Call:

coxph(formula = Surv(time, status) ~ ccr5 + strata(trans), data = silong)

coef exp(coef) se(coef) z p ccr5WM -0.7012 0.4960 0.1860 -3.77 0.000163

Likelihood ratio test=16.46 on 1 df, p=4.972e-05 n= 648, number of events= 220

(10 observations deleted due to missingness)

There are two alternative ways yielding the same result. First, we can actually leave out the *strata* term.

> coxph(Surv(time, status) ~ ccr5, data = silong)

Call:

coxph(formula = Surv(time, status) ~ ccr5, data = silong)

coef exp(coef) se(coef) z p ccr5WM -0.7012 0.4960 0.1860 -3.771 0.000163

Likelihood ratio test=16.46 on 1 df, p=4.964e-05 n= 648, number of events= 220

(10 observations deleted due to missingness)

Second, since the *strata* term is not needed we can use si.

> coxph(Surv(time, status != 0) ~ ccr5, data = si)

Call:

coxph(formula = Surv(time, status != 0) ~ ccr5, data = si)

```
coef exp(coef) se(coef) z p
ccr5WM -0.7013 0.4959 0.1860 -3.771 0.000163

Likelihood ratio test=16.47 on 1 df, p=4.953e-05
n= 324, number of events= 220
(5 observations deleted due to missingness)
```

Note: the actual estimated baseline hazards may be different, whether or not the strata term is used.

Assuming that baseline hazards for AIDS and SI are proportional (this is generally not a realistic assumption by the way, but just for illustration purposes).

```
> coxph(Surv(time, status) ~ ccr5WM.1 + ccr5WM.2 + factor(trans),
      data = silong)
Call:
coxph(formula = Surv(time, status) ~ ccr5WM.1 + ccr5WM.2 + factor(trans),
    data = silong)
                  coef exp(coef) se(coef)
ccr5WM.1
               -1.1664
                          0.3115
                                    0.3063 -3.808 0.00014
ccr5WM.2
               -0.3316
                          0.7178
                                    0.2366 -1.401 0.16112
factor(trans)2 -0.1843
                          0.8317
                                    0.1477 -1.248 0.21201
Likelihood ratio test=21.54 on 3 df, p=8.124e-05
n= 648, number of events= 220
   (10 observations deleted due to missingness)
Or, again using covariate by cause (transition) interaction.
> coxph(Surv(time, status) ~ ccr5 * factor(trans), data = silong)
coxph(formula = Surv(time, status) ~ ccr5 * factor(trans), data = silong)

```

Note that, even though patients are replicated in the long format, it is not necessary to use robust standard errors. Any of the previous analyses with the silong dataset gives identical results when a cluster(id) term is added. For instance,

```
> coxph(Surv(time, status) ~ ccr5 * factor(trans) + cluster(id),
+ data = silong)
```

Call:

```
coxph(formula = Surv(time, status) ~ ccr5 + factor(trans) + ccr5:factor(trans),
    data = silong, cluster = id)
```

```
coef exp(coef) se(coef) robust se

```

```
Likelihood ratio test=21.54 on 3 df, p=8.124e-05 n= 648, number of events= 220 \,
```

(10 observations deleted due to missingness)

gives the same result as before.

So far in the regression context we have just used the <code>coxph</code> function of the <code>survival</code> package. In order to obtain predicted cumulative incidences, <code>msprep</code> is useful. First let us store our analysis with separate covariate effects for the two causes.

```
> c1 <- coxph(Surv(time, status) ~ ccr5WM.1 + ccr5WM.2 + strata(trans),
+ data = silong, method = "breslow")</pre>
```

If we want the predicted cumulative incidences for an individual with CCR5 wild-type (WW), we make a *newdata* data frame containing the (transition-specific) covariate values for each of the transitions for the individual of interest. Then we apply *msfit* as illustrated earlier in the context of multi-state models.

```
> WW <- data.frame(ccr5WM.1 = c(0, 0), ccr5WM.2 = c(0, 0), trans = c(1, + 2), strata = c(1, 2))
> msf.WW <- msfit(c1, WW, trans = tmat)
```

And finally, to obtain the cumulative incidences we apply *probtrans*. Item [[1]] is selected because the prediction starts from state 1 (event-free) at time s = 0.

```
> pt.WW <- probtrans(msf.WW, 0)[[1]]</pre>
```

Similarly for an individual with the CCR5 mutant (WM) genotype.

```
> WM <- data.frame(ccr5WM.1 = c(1, 0), ccr5WM.2 = c(0, 1), trans = c(1, + 2), strata = c(1, 2))
> msf.WM <- msfit(c1, WM, trans = tmat)
> pt.WM <- probtrans(msf.WM, 0)[[1]]
```

We now plot these cumulative incidence curves for AIDS (pstate2) and SI appearance (pstate3), for wild-type (WW) and mutant (WM) in Figure 9 (Figure 5 in the tutorial).

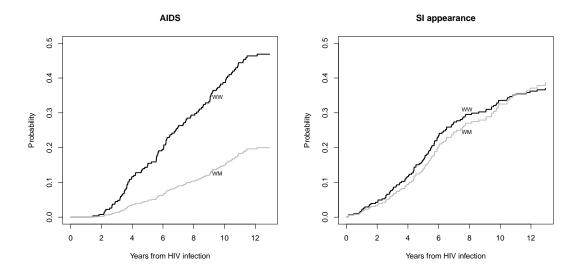

Figure 9: Cumulative incidence functions for AIDS (left) and SI appearance (right), for wild-type (WW) and mutant (WM) CCR5 genotype, based on a proportional hazards model on the cause-specific hazards.

The illustration of the phenomenon that the same cause-specific hazard ratio may have different effects on the cumulative incidences (Figure 7 in the tutorial) may be performed as well, by replacing the appropriate parts of the cumulative hazard of AIDS (trans=1), and calling probtrans. We are interested in SI appearance and adjust the hazards of the competing risk (AIDS) while keeping the remainder the same (Figure 7 in the tutorial). The result is shown in Figure 10. We multiply the baseline hazard of AIDS with factors (ff = 0, 0.5, 1, 1.5, 2, 4).

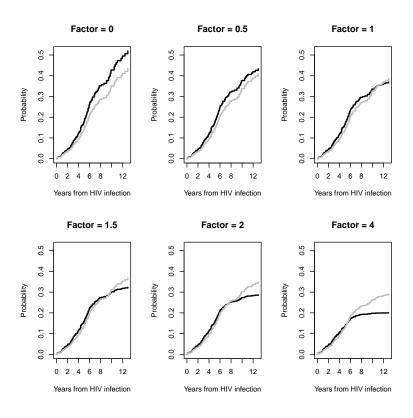

Figure 10: Cumulative incidence functions for Si appearance, for CCR5 wild-type WW (black) and mutant WM (grey). The baseline hazard of AIDS was multiplied with different factors, while keeping everything else the same.

```
+ idx2 <- (pt.WM$time < 13)
+ plot(c(0, pt.WW$time[idx1]), c(0, pt.WW$pstate3[idx1]), type = "s",
+ ylim = c(0, 0.52), xlab = "Years from HIV infection",
+ ylab = "Probability", lwd = 2)
+ lines(c(0, pt.WM$time[idx2]), c(0, pt.WM$pstate3[idx2]),
+ type = "s", lwd = 2, col = 8)
+ title(main = paste("Factor =", ff))
+ }
> par(mfrow = c(1, 1))
```

Fine and Gray regression on cumulative incidence functions is not implemented in *mstate*, but in the R package *cmprsk*. Since our main purpose here is illustration of *mstate*, we just give the code and the output.

```
> library(cmprsk)
> sic <- si[!is.na(si$ccr5),]
> ftime <- sic$time
> fstatus <- sic$status
> cov <- as.numeric(sic$ccr5)-1
> # for failures of type 1 (AIDS)
> z1 <- crr(ftime,fstatus,cov)
> z1
```

convergence: TRUE

```
coefficients:
  cov1
-1.004
standard errors:
[1] 0.295
two-sided p-values:
   cov1
0.00066
> # for failures of type 2 (SI)
> z2 <- crr(ftime,fstatus,cov,failcode=2)
> z2
convergence: TRUE
coefficients:
   cov1
0.02359
standard errors:
[1] 0.2266
two-sided p-values:
cov1
0.92
The result (Figure 8 in the tutorial) is shown in Figure 11.
> z1.pr <- predict(z1,matrix(c(0,1),2,1))
> # this will contain predicted cum inc curves, both for WW (2nd column) and WM (3rd)
> z2.pr <- predict(z2,matrix(c(0,1),2,1))
> # Standard plots, not shown
> par(mfrow=c(1,2))
> plot(z1.pr,lty=1,lwd=2,color=c(8,1))
> plot(z2.pr,lty=1,lwd=2,color=c(8,1))
> par(mfrow=c(1,1))
> ## AIDS
> n1 <- nrow(z1.pr) # remove last jump</pre>
> plot(c(0,z1.pr[-n1,1]),c(0,z1.pr[-n1,2]),type="s",ylim=c(0,0.5),
      xlab="Years from HIV infection",ylab="Probability",lwd=2)
> lines(c(0,z1.pr[-n1,1]),c(0,z1.pr[-n1,3]),type="s",lwd=2,col=8)
> title(main="AIDS")
> text(9.3,0.35,"WW",adj=0,cex=0.75)
> text(9.3,0.14,"WM",adj=0,cex=0.75)
> ## SI appearance
> n2 <- nrow(z2.pr) # again remove last jump
> plot(c(0,z2.pr[-n2,1]),c(0,z2.pr[-n2,2]),type="s",ylim=c(0,0.5),
      xlab="Years from HIV infection", ylab="Probability", lwd=2)
> lines(c(0,z2.pr[-n2,1]),c(0,z2.pr[-n2,3]),type="s",lwd=2,col=8)
> title(main="SI appearance")
> text(7.9,0.28,"WW",adj=0,cex=0.75)
> text(7.9,0.31,"WM",adj=0,cex=0.75)
```

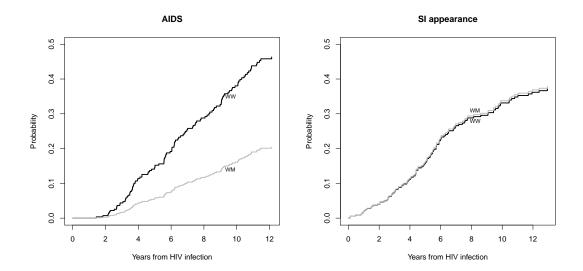

Figure 11: Cumulative incidence functions for AIDS (left) and SI appearance (right), for CCR5 wild-type WW and mutant WM, based on the Fine and Gray model.

To judge the "fit" of the cause-specific and Fine & Gray regression models we estimate cumulative incidence curves nonparametrically, i.e., for two subgroups of WW and WM CCR5-genotypes. Here we can use the *group* argument of *Cuminc*.

```
> ci <- Cuminc(si$time, si$status, group = si$ccr5)
> ci.WW <- ci[ci$group == "WW", ]
> ci.WM <- ci[ci$group == "WM", ]</pre>
```

We show these nonparametric estimates in Figure 12 (Figure 9 in the tutorial).

```
> idx1 <- (ci.WW$time < 13)</pre>
> idx2 <- (ci.WM$time < 13)</pre>
> plot(c(0, ci.WW\$time[idx1]), c(0, ci.WW\$CI.1[idx1]), type = "s",
      ylim = c(0, 0.5), xlab = "Years from HIV infection", <math>ylab = "Probability",
      1wd = 2
> lines(c(0, ci.WM$time[idx2]), c(0, ci.WM$CI.1[idx2]), type = "s",
      1wd = 2, col = 8)
> title(main = "AIDS")
> text(9.3, 0.35, "WW", adj = 0, cex = 0.75)
> text(9.3, 0.11, "WM", adj = 0, cex = 0.75)
> plot(c(0, ci.WW\$time[idx1]), c(0, ci.WW\$CI.2[idx1]), type = "s",
      ylim = c(0, 0.5), xlab = "Years from HIV infection", <math>ylab = "Probability",
      1wd = 2
> lines(c(0, ci.WM$time[idx2]), c(0, ci.WM$CI.2[idx2]), type = "s",
      1wd = 2, col = 8)
> title(main = "SI appearance")
> text(7.9, 0.32, "WW", adj = 0, cex = 0.75)
> text(7.9, 0.245, "WM", adj = 0, cex = 0.75)
```

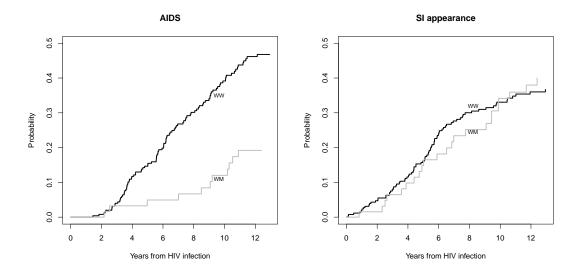

Figure 12: Non-parametric cumulative incidence functions for AIDS (left) and SI appearance (right), for CCR5 wild-type WW and mutant WM.
